(Received August 3/October 10, 1989)

Summary: In forty-nine subjects on maintenance haemodialysis quantitative information with respect to changes in the erythron was derived from the red blood cell size distribution histogram. Increased values for the fraction of microcytes were observed in seventeen subjects, whereas in three subjects increased fractions of macrocytes were established. Both fractions were found to be increased simultaneously in only one subject. In the case of normal mean corpuscular volume (MCV) values, the fractions of microcytes were shown to be increased in four male and three female subjects. In contrast, MCV values were increased in four male subjects while the fractions of macrocytes did not exceed the reference range.

Several causes which may give rise to abnormalities in red blood cell size distribution histograms in subjects treated by haemodialysis are discussed. From the interpretation of results for serum ferritin concentration, serum iron concentration, total iron binding capacity, and iron saturation percentage it is difficult to establish unequivocally whether the iron supply to the patient is appropriate.

Introduction

In subjects on chronic haemodialysis, therapeutic intervention would be more successful if factors which may contribute to the failure of erythropoiesis were better understood. In several conditions, red blood cell indices may be within the reference range, whereas microcytic red blood cells are increased (1). In subjects

treated by maintenance haemodialysis, increased proportions of microcytic red blood cells may be found due to iron deficiency or aluminium intoxication (2). Occasionally an increased proportion of macrocytic red blood cells can be observed (3). Iron deficiency may frequently prevail as a complication of chronic haemodialysis (4). The main causes are blood loss on the dialysis membrane and bleeding secondary to uraemic gastroenteritis and platelet dysfunction. From the generally used laboratory tests to establish iron deficiency, the determination of the serum ferritin concentration is considered to be the most suitable when checked regularly, e. g. at monthly or bimonthly intervals (3, 5). Maintaining the serum ferritin con-

- ADW_{0.5} = absolute distribution width at half peak height

centration within certain limits by iron supplementation or treatment with desferrioxamine would minimize the risk of iron deficiency or haemosiderosis (6–8).

Drawbacks of the currently available tests for the detection of abnormalities in erythropoiesis (9, 10) have stimulated us to perform additional haemocytometric investigations. In particular, we have derived quantitative information from red blood cell size distribution histograms. Values established for the fractions of microcytes and macrocytes and values for the absolute distribution width at half peak height ($ADW_{0.5}$) are considered in this paper, together with the results of determinations reflecting the iron status.

Subjects and Methods

Blood samples were drawn in Venoject® vacuum tubes, anti-coagulated with K_3EDTA (Terumo Europe N. V., 3030 Leuven, Belgium). Haemocytometric data, including the $ADW_{0.5}$ value and the fractions of microcytes and macrocytes were determined by means of an Ortho ELT 800 WS® Hematology Analyser according to the instructions in the operator reference manual (11).

Absolute distribution width at half peak height

The $ADW_{0.5}$ values are measured from the histogram and expressed in femtolitres (fl) by using a conversion factor (12).

Procedure for determination of the fractions of microcytes and macrocytes

A mean red blood cell size distribution histogram for apparently healthy subjects has been calculated previously, in order to establish a threshold corresponding approximately to the 2.5th and 97.5th percentile, thereby arbitrarily limiting the fractions of microcytes and macrocytes. The threshold units are expressed in voltage channel numbers. In the reference curve the 2.5th and 97.5th percentile are found to correspond to channel number 21 and 35 respectively, representing red blood cell volumes of 65 and 108 fl. These channel numbers are assumed to be the limits of the fractions of microcytes and macrocytes respectively. The fraction of red blood cells below the lower threshold is considered to be the fraction of microcytes, whereas the upper threshold is used for the discrimination of the fraction of macrocytes. Once the discrimination limits have been established, the fractions of microcytes and macrocytes were calculated separately for each subject.

Iron status

Serum iron concentration and total iron binding capacity were determined by standard routine methods. Serum iron concentration is determined by using ferene as an indicator. Interference of copper is eliminated by addition of thiourea to the reagent (13). For determination of the iron binding capacity, excess ferric chloride is added to the serum sample in order to saturate the transferrin. Excess of free Fe^{3+} -ions are removed by precipitation using magnesium hydroxy carbonate powder (14). The total iron binding capacity was determined by analysing the iron concentration in the supernatant. Serum ferritin

concentration was assayed with the TANDEM-E-FER-kit (Hybritech, San Diego, CA 92126), a two site enzymimmunometric assay. Vitamin B_{12} and folate were determined with the Simul-trac-kit (Becton & Dickinson, Immunodiagnosics, Orangeburg, NY 10962).

Reference group

For establishing reference ranges, blood samples were collected from 72 apparently healthy males (19–53 years old) and 65 apparently healthy females (20–45 years old).

Haemodialysis patients

Twenty-two males and twenty-seven females with chronic renal insufficiency, under treatment by chronic intermittent haemodialysis for end-stage renal disease, were investigated. About 30% of this group incidentally received transfusions amounting to two units of red blood cells concentrates. The time frequency of blood transfusion varied between once every 4 weeks and once every 6 months. The ages of the subjects ranged from 35 to 83 years. Haemodialysis was performed two times a week for four hours. Blood samples were collected after finishing haemodialysis treatment.

Results

Haemocytometric values and results for serum concentrations reflecting iron, folate and vitamin B_{12} status for male and female subjects were processed separately, because sex-dependent variations may be present. The results for subjects receiving blood transfusions were similar to those for the other subjects. Ranges of haemocytometric values established for reference subjects and subjects treated by haemodialysis are shown in table 1.

Individual haemocytometric results, viz. Hb, red blood cell, MCV and $ADW_{0.5}$ values, are depicted in figure 1. Limits of reference ranges are indicated in the figure. Results for male and female subjects are plotted separately. In all subjects except one, Hb¹⁾ and red blood cell concentrations are obviously decreased. MCV¹⁾ values are decreased in five males and five females. Increased $ADW_{0.5}$ ¹⁾ values were observed in seven male subjects and three female subjects. Decreased $ADW_{0.5}$ values are apparent in two male and four female subjects.

As shown in figure 2, nine male subjects and eight female subjects showed increased values for the fraction of microcytes. Normal MCV values were established in 4 of these males and 3 of these females. The fraction of macrocytes was increased in two males and in one female (fig. 3).

Serum concentrations of compounds reflecting the iron, folate and vitamin B_{12} status are shown in table 2. Results of individual determinations reflecting the iron status are depicted in figure 4. Increased serum

Tab. 2. Serum concentrations of compounds reflecting the iron, folate and vitamin B₁₂ status for reference subjects and subjects treated by haemodialysis. Ranges, arbitrarily limited by the 2.5th and 97.5th percentile (90% confidence limits) are shown together with the mean value (\bar{x}). In both cases the results were established separately for male and female subjects.

| | Unit | Reference subjects' group | | Subjects treated by maintenance haemodialysis | | | | | |
|---------------------------------------|-------------------|---------------------------|--------|---|--------|------------------|--------|-----------|------|
| | | males (n = 72) | | males (n = 22) | | females (n = 27) | | | |
| | | P 2.5 | P 97.5 | P 2.5 | P 97.5 | P 2.5 | P 97.5 | \bar{x} | |
| Serum iron concentration | $\mu\text{mol/l}$ | 10.2 | 23.3 | 3.6 | 10.2 | 3.5 | 10.2 | 10.2 | 24.3 |
| Total iron binding capacity | $\mu\text{mol/l}$ | 50 | 73 | 42 | 58 | 40 | 55 | 55 | 68 |
| Percent saturation | | 17 | 40 | 7 | 18.5 | 6 | 19.1 | 19.1 | 48 |
| Ferritin concentration | $\mu\text{g/l}$ | 32 | 168 | 24 | 311 | 64 | 731 | 731 | 3500 |

The upper levels of the reference ranges for the fraction of macrocytes and the MCV value are indicated in the figure for both males and females.

Fig. 4. Scattering of results established for serum ferritin concentration ($\mu\text{g/l}$), serum iron concentration ($\mu\text{mol/l}$), total iron binding capacity ($\mu\text{mol/l}$) and percentage saturation (%).
● male subject treated by maintenance haemodialysis
x female subject treated by maintenance haemodialysis
The limits of the reference ranges are indicated in the figures.

ferritin concentrations are shown in nine (about 41%) of the males and in 22 (about 80%) of the females. Decreased serum iron concentrations are shown in fourteen males and six females. Total iron binding capacity values are increased in four males and borderline in one female subject. Iron saturation was decreased in a high number of subjects, viz. eleven males and three females.

Discussion

Haemocytometric determinations in subjects treated by haemodialysis were performed in order to obtain additional information with respect to disturbances in erythropoiesis. Blood samples for our study were collected after finishing the haemodialysis treatment. Experiments concerning the characteristics of the red blood cells in their prehaemodialysis environment were not performed.

In 19 out of 49 subjects abnormalities in red blood cells size distribution histograms were detected. Several conditions which may result in the production of increased amounts of microcytes or macrocytes are discussed below.

Alterations in erythropoiesis

Red blood cell concentrations

As shown in figure 1 concentrations of red blood cells are drastically reduced in subjects treated by maintenance haemodialysis. Similar results have been discussed elsewhere (15). Suppression of erythropoiesis may be due to accumulation of uraemic toxins, a decreased pH, an increased concentration of inorganic phosphate or to a decreased concentration of erythropoietin (3). Erythropoiesis may further be decreased as a result of iron or folate deficiency.

Degree of red blood cell volume dispersion

Increased $ADW_{0.5}$ values, demonstrating a red blood cell population with an increased degree of volume dispersion are observed in 11 subjects. Decreased $ADW_{0.5}$ values are observed in 9 subjects. A decreased value for the red blood cell volume dispersion can be explained as follows. In less favourable conditions, red blood cells may acquire a membrane abnormality known as "burrings", alternatively called "echinocytosis" (16). With respect to light scattering intensity, echinocytes resemble spheroid red blood cells. It has been suggested elsewhere that preserved red blood cells show considerably less volume dispersion after ageing (17, 18) and after spheroiding (19).

The fraction of macrocytes

As may be concluded from the results depicted in figure 3 MCV values are increased in six subjects, whereas the fraction of macrocytes was increased in only three subjects. The size distributions show an increased degree of skew to the left, whereas the modal peak channel number is shifted to the right (own observation).

Neither decreased concentrations of folate in serum nor decreased vitamin B₁₂ concentrations could be detected in our subject group (tab. 2). Chronic disease in some cases combined with folate deficiency, sideroachresia or defects in the synthesis of the red blood cell membrane may yield possible explanations for the presence of macrocytes (20).

The fraction of microcytes

In seven subjects receiving maintenance haemodialysis, increased values were established for the fraction of microcytes, whereas MCV values were within the reference range. For the detection of several abnormalities, e.g. red blood cell fragmentation, poikilocytosis and minor changes in red blood cells volume dispersion, evaluation of the red blood cell size distribution histogram is supposed to be more reliable than the technician-dependent examination of the blood film (21).

Iron stores

Iron deficiency

In our study decreased serum iron concentrations were found in many subjects (fig. 4). Since intra-individual fluctuations may be relatively large the reliability of this analyte for diagnostic purposes is rather low.

Total iron binding capacity was found to be slightly increased in only 3 male subjects. In two of these the serum ferritin concentration was decreased. Iron deficiency may develop readily in subjects treated by chronic haemodialysis unless special precautions are taken. In subjects with chronic disease the serum ferritin concentration may be disproportionately increased in relation to marrow iron stores (10). Adequacy of iron stores as reflected by the serum ferritin concentrations may vary considerably according to the investigator and laboratory method used for the determination. In a study by Docci (7) haemodialysis patients with serum ferritin concentrations less than 65 µg/l showed a positive response to parenteral iron administration. However, a significant increase of Hb concentration was also detected in subjects with serum

ferritin concentrations ranging from 65 to 160 µg/l. Depletion of iron stores at an early stage might be clear from deviations in red blood cell size distribution histograms (4, 22).

Iron overload

When compared with the reference range, serum ferritin concentrations were increased in 31 subjects. In 6 of these subjects the serum ferritin concentration exceeded 1000 µg/l. A markedly increased serum ferritin concentration may be a typical indication of early haemochromatosis.

Aluminium intoxication

Aluminium accumulation in patients undergoing haemodialysis may result, among other things, in the

production of microcytic red blood cells (3). The mechanisms by which aluminium overload causes microcytic anaemia are unknown (2). This phenomenon was not further investigated in the present study.

Conclusion

In accordance with the results of a previous study (1), increased values for the fraction of microcytes are shown to be a more sensitive indicator for aberrations in red blood cell size distributions than MCV values. In the case of a normal red blood cell size distribution more extensive testing should be omitted, whereas in other cases aberrations in size distribution histograms may be a guideline for a more appropriate selection of patients for further investigations.
